Paradox of Enrichment: Destabilization of Exploitation Ecosystems in Ecological Time

Abstract. Six reasonable models of trophic exploitation in a two-species ecosystem whose exploiters compete only by depleting each other's resource supply are presented. In each case, increasing the supply of limiting nutrients or energy tends to destroy the steady state. Thus man must be very careful in attempting to enrich an ecosystem in order to increase its food yield. There is a real chance that such activity may result in decimation of the food species that are wanted in greater abundance.

THE PARADOX OF THE PLANKTON*

G. E. HUTCHINSON

Osborn Zoological Laboratory, New Haven, Connecticut

Critiques de Rosenzweig-MacArthur

Paradoxe du plancton

The problem that is presented by the phytoplankton is essentially how it is possible for a number of species to coexist in a relatively isotropic or unstructured environment all competing for the same sorts of materials. The problem is particularly acute because there is adequate evidence from enrichment experiments that natural waters, at least in the summer, present an environment of striking nutrient deficiency, so that competition is likely to be extremely severe.

According to the principle of *competitive exclusion* (Hardin, 1960) known by many names and developed over a long period of time by many investigators (see Rand, 1952; Udvardy, 1959; and Hardin, 1960, for historic reviews), we should expect that one species alone would outcompete all the others so that in a final equilibrium situation the assemblage would reduce to a population of a single species.

Modèle Ratio-dépendant

Le modèle ratio dépendant proposé en 1989 est une (assez) bonne réponse à toutes ces questions. Il consiste simplement à remplacer $Mu(x)$ par $Mu(x/y)$ ce qui a l'avantage de ne pas rajouter de paramètres au modèle.

Un longue polémique à propos de ce modèle s'est développée, elle n'est pas terminée mais un large consensus s'est quand même dégagé pour le considérer comme pertinent.

Modèle Ratio-dépendant

$$\dot{x} = f(x) - \frac{1}{Y} \mu(x, y) \cdot y$$

$$\dot{y} = \mu(x, y) \cdot y - \nu(y) \cdot y$$

$\frac{1}{Y} \mu(x, y) =$ Quantité de ressource prélevée par $\begin{cases} \text{par consommateur} \\ \text{unité de temps} \end{cases}$

1. Fonction de la "quantité des ressource" uniquement :

$$x \mapsto \mu(x) \quad (\mathbf{R-MA})$$

2. Fonction de la "quantité de ressource par consommateur":

$$x \mapsto \mu(x/y) \quad (\mathbf{A-G})$$

Kinetics of Bacterial Growth: Relationship between Population Density and Specific Growth Rate of Continuous Cultures

By D. E. CONTOIS*

Department of Marine Biology, University of California, La Jolla, California, U.S.A.

SUMMARY: Results from studies of continuous cultures of *Aerobacter aerogenes* growing in chemically defined media indicate that specific growth rate (R) is a function of population density (P) as well as the concentration of the limiting nutrient (S). From these observations, and those of others, the following model for bacterial growth is derived:

$$R = \frac{u_m S}{B P + S}$$

where u_m and B are growth parameters that are constants under defined conditions. This model is believed to have general applicability and to account for bacterial growth in both batch and continuous cultures.

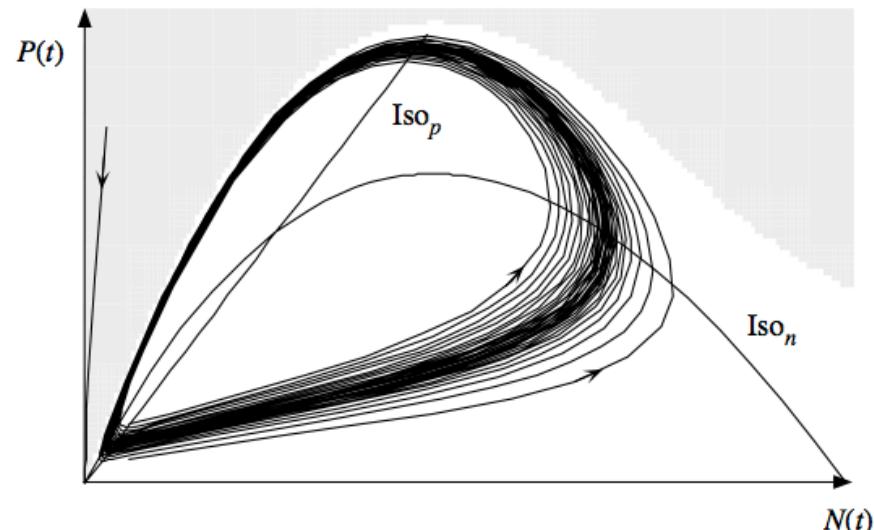

Figure 4. The non-trivial equilibrium is unstable and $(0, 0)$ becomes attractive, $S > Q + R$. There are two attractors, a stable limit cycle and $(0, 0)$. Parameter values are $R = 0.5$, $Q = 0.79$, $S = 1.78$.

form of the separatrix. This figure also shows that the limit cycles will be very sensitive to stochastic influences: random perturbations to the populations occurring while the cycle is not far from the separatrix can bring the trajectory into the basin of attraction of $(0, 0)$, thereby causing extinction. Figure 5 shows the case when

Cascades de chemostats

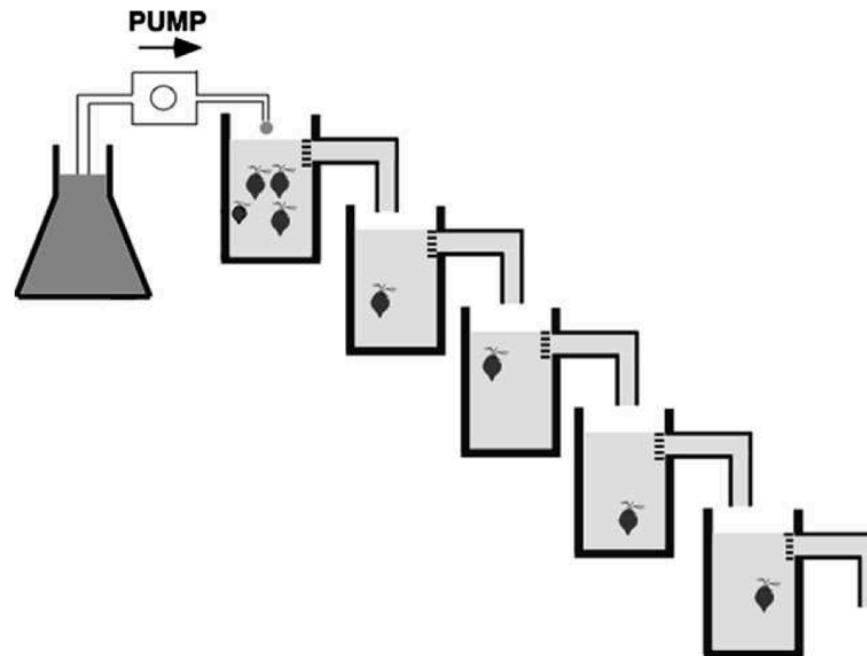

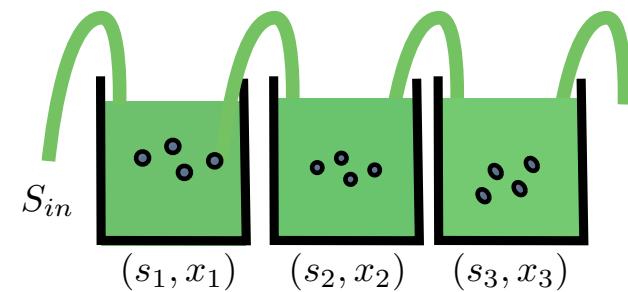

Figure 4.1. General experimental setup of the cascade of five chambers. Algae are pumped at constant flow from a stirred tank into the cascade. Starting with an inoculum of cladocerans in each chamber, populations increase or decline until an equilibrium is reached after a few weeks. Filters prevent the passage of newborn cladocerans through the cascade. After Arditi and Saïah (1992), with permission of the Ecological Society of America.

Cascades de chemostats

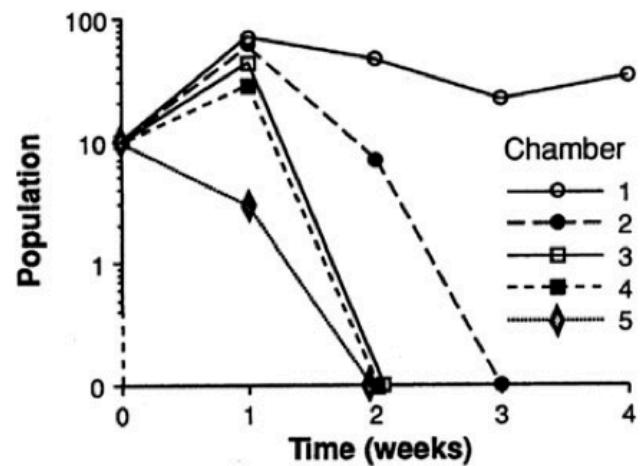

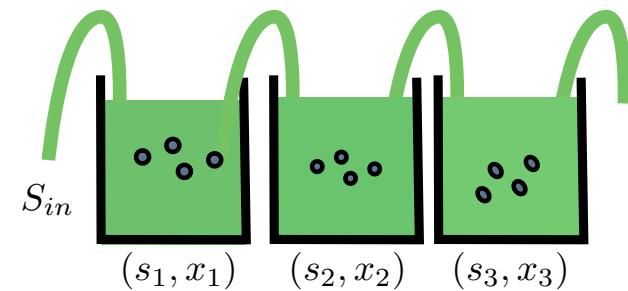

Figure 4.2. Population dynamics (log scale) of *Daphnia magna* in the five chambers of the cascade. With the exception of the first chamber, all populations declined to extinction, as predicted by the prey-dependent hypothesis. After Arditi and Saïah (1992), with permission of the Ecological Society of America.

Cascades de chemostats

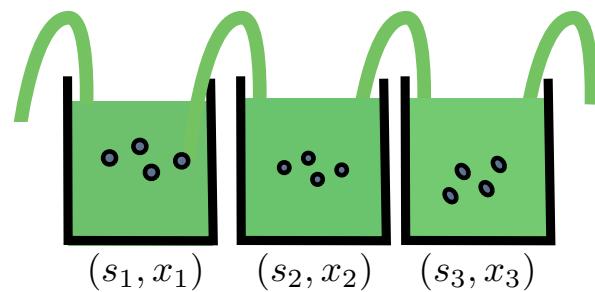

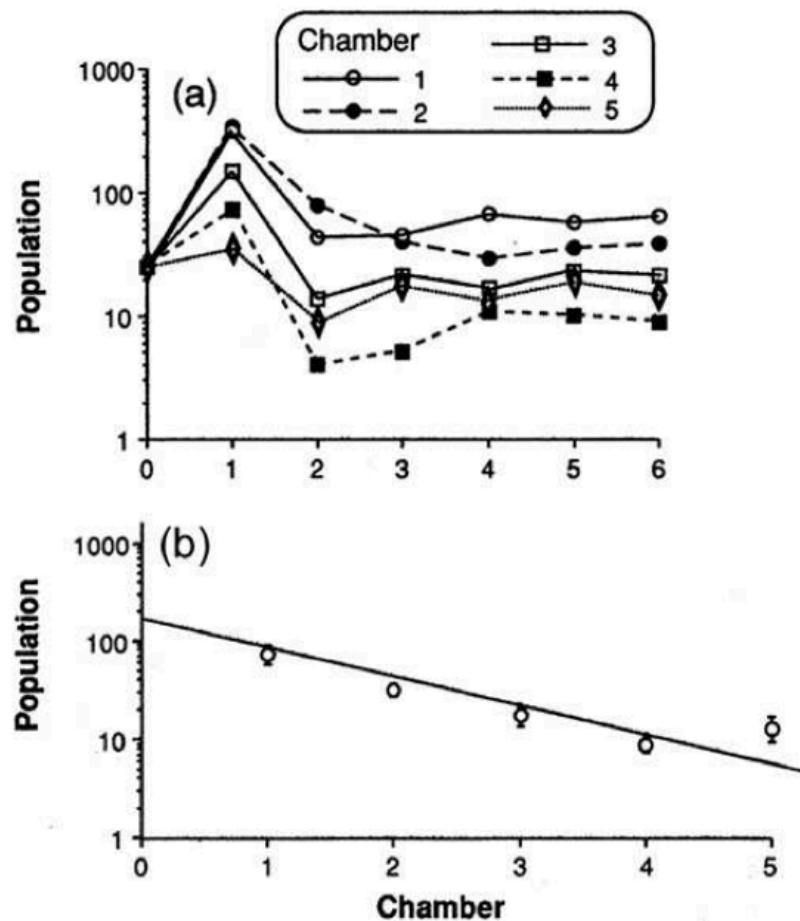

Figure 4.3. (a) Population dynamics (log scale) of *Simocephalus vetulus* in the five chambers of the cascade. All populations stabilized. (b) Population equilibria (log scale) in each chamber. Each point is the average of six values (last three weeks of two replicates). The equilibria follow approximately a geometric sequence, as predicted by the ratio-dependent hypothesis. After Arditi and Saïah (1992), with permission of the Ecological Society of America.
